(Dated: February 2, 2008)

We report an electrical transport study in Ca$_{2-x}$Sr$_x$RuO$_4$ single crystals at high magnetic fields (B). For x = 0.2, the Hall constant $R_{xy}$ decreases sharply at an anisotropic metamagnetic (MM) transition reaching its value for Sr$_2$RuO$_4$ at high fields. A sharp decrease in the A coefficient of the resistivity $T^2$-term and a change in the structure of the angular magnetoresistance oscillations (AMRO) for B rotating in the planes, confirms the reconstruction of the Fermi surface (FS). Our observations and LDA calculations indicate a strong dependence of the FS on the Ca concentration and suggest the coexistence of itinerant and localized electronic states in single layerd ruthenates.

PACS numbers: 72.15.-v, 71.30.+h, 72.15.Gd, 72.25.Ba

The single layered ruthenates Ca$_{2-x}$Sr$_x$RuO$_4$ have a quite complex phase-diagram as function of doping x $\leq 0.2$. While Sr$_2$RuO$_4$ is a rare example of a well-defined two-dimensional Fermi liquid (FL) [3, 4] displaying spin-triplet superconductivity, the complete replacement of Sr by the isovalent element Ca produces to the Mott insulator Ca$_2$RuO$_4$ [1, 2]. A series of correlated metallic states are protracted between both extremes.

In this system the relevant 4$d$-orbitals belong to the $t_{2g}$-subshell and are degenerate. The planar structure conducts to very weak hybridization between orbitals which have either even ($d_{xy}$, $d_{yz}$, $d_{zx}$) parity under the reflection $z \rightarrow -z$. These orbitals lead in Sr$_2$RuO$_4$ to a Fermi surface composed by three warped cylinders [1]. The $\alpha$ and $\beta$ sheets arise from 1D chains of $d_{yz}$, $d_{zx}$ orbitals while the $\gamma$ FS sheet originates from a 2D network of planar $d_{xy}$ orbitals. Starting from the undistorted Sr$_2$RuO$_4$, Ca substitution initially stabilizes the rotation of RuO$_6$ octahedra. This induces an enhancement of both the low T magnetic susceptibility $\chi(T)$ and the Sommerfeld coefficient characterizing the electronic contribution to the specific heat $\gamma$. Both quantities display a pronounced maximum at a critical value $x_c \approx 0.5$ where the crystallographic structure of the Ca$_{2-x}$Sr$_x$RuO$_4$ series changes from tetragonal to orthorhombic through a second-order structural transition [5]. For stronger Ca concentrations and as we approach the Mott transition at $x \lesssim 0.2$, $\chi(T)$ is strongly suppressed by the emergence of AF correlations.

This complex evolution has led to various theoretical proposals, in particular to the idea that some of the $d$-orbitals display localized spin and orbital degrees of freedom, while others provide itinerant carriers. This so-called orbital-selective Mott transition (OSMT) [8] could, for instance, explain the experimental observation of an effective spin $S$ very close to the value 1/2 for 0.2 ≤ x ≤ 0.5 [4], which is difficult to understand within an entirely itinerant description. However the concept of orbital-selective Mott-transition was challenged by the dynamical mean field (DMFT) calculations of Liebsch [8] which suggest that two bands of different widths coupled by electron-electron interactions always undergo a single simultaneous Mott transition. Koga et al. claim that this apparent discrepancy can be solved by taking into account a finite Hund coupling in Hubbard models considering multiple bands with different bandwidths [10]. In contrast, according to Okamoto and Mills [11] Hund coupling would in fact stabilize a given system against orbital ordering preventing the occurrence of the OSMT. Finally, a recent photoemission study in Ca$_{1.5}$Sr$_{0.5}$RuO$_4$ finds that the geometry of the $\alpha$ and $\beta$ FS sheets remains almost unchanged respect to Sr$_2$RuO$_4$, with the $\gamma$ sheet exhibiting a hole-like FS in contrast to being electron-like in the pure Sr compound [12]. The observation of all three volume conserving FS sheets would demonstrate the absence of OSMT in Ca$_{1.5}$Sr$_{0.5}$RuO$_4$.

To clarify the possible existence of localized carriers within a metallic $d$-electron system as proposed by the orbital-selective Mott-transition model, we performed a detailed electrical transport study at high magnetic fields in Ca$_{2-x}$Sr$_x$RuO$_4$ single crystals for x = 0.2 and 0.5. In particular, we studied the Hall effect and the angular dependence of the magnetoresistance or AMRO, which is a technique commonly used to define the relatively simple two-dimensional (2D) FS of layered organic metals [13], and which has already provided valuable information about the FS of Sr$_2$RuO$_4$ [14, 15]. Our measurements reveal a profound modification of the original FS of Sr$_2$RuO$_4$ upon Ca doping and a severe reconstruction of the FS for $x = 0.2$ at a metamagnetic transition. These observations are consistent with the proposed existence of localized $d$-electronic states in Ca$_{2-x}$Sr$_x$RuO$_4$.
changing of its inter-plane resistivity (for 0.2 ≤ x ≤ 0.5).

The upper panel of Fig. 1 shows the in-plane resistivity of Ca$_{1.8}$Sr$_{0.2}$RuO$_4$ single crystal at T = 22 mK and as a function of the field B applied along the inter-plane direction. While the lower panel of Fig. 1 shows the relative change of its inter-plane resistivity ρ$_{zz}$ normalized with respect to its zero field value ρ$_0$, as a function of the external field B oriented along different crystallographic orientations and at T ≈ 0.6. In both panels a pronounced peak is observed at an anisotropic metamagnetic transition.

FIG. 1: Upper panel: In-plane resistivity ρ for a Ca$_{1.8}$Sr$_{0.2}$RuO$_4$ single crystal as a function of the field B applied along the inter-plane direction at T = 22 mK. Lower panel: Inter-plane resistivity ρ$_{zz}$ normalized with respect to its zero field value ρ$_0$, as a function of the external field B oriented along different crystallographic orientations and at T ≈ 0.6. In both panels a pronounced peak is observed at an anisotropic metamagnetic transition.

may be composed by both electron and hole FS sheets, increase in scattering events. Thus, the increase in condensation of an orbital-ordered state [21]. Similarly, in the Ca
behavior bears similarities with the metamagnetism fol-
interpreted as a change in FS volume, this metamagnetic transition is crossed. b) FIG. 3: a) Inter-plane resistance $R_{xz}$ as a function of the angle $\phi$ between $B$ and an in-plane axis for a Ca$_{1.8}$Sr$_{0.2}$RuO$_4$ single crystal at $T = 0.6$ K. Notice how the low field two-fold periodicity progressively becomes four-fold at high fields after the metamagnetic transition is crossed. b) $R_{xz}$ for a Sr$_2$RuO$_4$ single crystal as function of the angle $\phi$ and for several values of $B$ and at $T \simeq 50$ mK. Notice the progressive emergence of a new periodicity at higher fields. In both graphs, all curves are vertically displaced for clarity.

ing mechanism. Notice how the absolute value of $R_{xy}$ decreases through the metamagnetic transition from nearly $2.5 \pm 0.5 \times 10^{-10}$ m$^3$/C at very low fields and saturates at the value of $\simeq 1 \pm 0.05 \times 10^{-10}$ m$^3$/C, which is precisely the value reported for Sr$_2$RuO$_4$ [20]. This indicates an important modification of the original band structure of Sr$_2$RuO$_4$ upon Ca doping as well as a severe reconstruction of the FS at the metamagnetic transition. The Hall mobility $R_{xy}/\rho$ decreases rapidly from $\sim 6.5$ cm$^2$/Vs at $B = 0$ to a value of about $\sim 1.5$ cm$^2$/Vs at $B_{MM}$ saturating at high $B$s to a value of $\sim 4.0$ cm$^2$/Vs reflecting an increase in scattering events. Thus, the increase in conductivity above the transition cannot be attributed to an increase in mobility, but it reflects perhaps the reduction in the effective mass of the charge carriers. Notice that in multi-band systems such as the ruthenates, whose FS may be composed by both electron and hole FS sheets, $R_{xy}$ is no longer $\propto n_c^{-1}$ where $n_c$ is the number of charge carriers. Although the abrupt change in $R_{xy}$ cannot be interpreted as a change in FS volume, this metamagnetic behavior bears similarities with the metamagnetism followed by colossal magnetoresistive-like behavior seen in the Ca$_3$Ru$_2$O$_7$ system and which is ascribed to the destabilization of an orbital-ordered state [21]. Similarly, in our case it could also indicate the existence of localized $d$-electron states that are destabilized by the external field.

Figure 3(a) shows the inter-plane resistance $R_{zz}$ of a Ca$_{1.8}$Sr$_{0.2}$RuO$_4$ single crystal at $T = 0.6$ K and as a function of the azimuthal angle $\phi$ between $B$ and an in-plane axis for several values of $B$ below and above $B_{MM}$ (as indicated in the figure). All curves are vertically displaced for clarity. At low fields, $R_{zz}(\phi)$ is essentially two-fold. A similar magnetoresistive effect, but displaying four-fold periodicity (that reflects the angular symmetry of the CuO$_2$ planes which leads to a four-fold modulation in $k_F$, $v_F$ and $\tau$), was reported in the tetragonal compound Tl$_2$Ba$_2$CuO$_6$ [22] as well as in Sr$_2$RuO$_4$ [15]. Here, the two-fold sinusoidal-like dependence, which reflects the symmetry of the orthorhombic structure, progressively disappears as the MM-transition is approached. As $B$ further increases a new, nearly four-fold, periodicity emerges. This unique evolution of the AMRO data across the MM-transition is consistent with the reconstruction of the FS revealed by $R_{xy}$. It cannot be simply explained in terms semiclassical orbits exploring the geometry of the FS in greater detail at higher fields. To illustrate this point in Fig. 3(b) we show $R_{zz}(\phi)$ for a Sr$_2$RuO$_4$ single crystal at $T = 50$ mK and for several values of $B$ (traces are vertically displaced for clarity). At lower $B$s one clearly observes the four-fold AMRO but as $B$ increases its amplitude increases with a new periodicity emerging and overlapping it. The new structure reflecting the warping of the FS, does not emerge in detriment of the lower field one(s), contrary to the $x = 0.2$ case. More importantly, even above the metamagnetic transition the symmetry of the FS for $x = 0.2$ remains essentially two- and not four-fold.

A two-dimensional FS composed of three open cylinders, as seen by ARPES for $x = 0.5$, would generate a distinctive polar AMRO ($\rho_{zz}(\theta, B)$ where $\theta$ is the angle between $B$ and the c-axis), as seen for instance, in Sr$_2$RuO$_4$ [14]. For very low levels of disorder, one should observe...
a series of peaks, periodic in $\tan(\theta)$, due to the Yamaji
effect. While for disordered systems one might ob-
serve only a small amplitude single sinusoidal component
showing a minimum for $B \parallel c$-axis. Nevertheless, as seen in
Fig. 4 which shows $R_{22}(\theta)$ at $T = 0.6$ K and for
several field values, a very pronounced AMRO is indeed
observed for $x = 0.2$ but it does not display an angular
structure compatible with the above discussion. A quite
similar but far less pronounced AMRO (as well as MM
behavior) is observed also in $x = 0.5$ (not shown here).
The origin of the observed dependence remains unclear,
although it is similar to that of the so-called Lebed oscil-
lations seen in quasi-one-dimensional organic conductors
[24]. Were this their correct description, it would imply
that the 2D $\gamma$ FS sheet has moved below $\rho(\epsilon_F)$ while the
$\alpha$ and/or the $\beta$ Q1D FS sheets would survive this level of
doping. Quasi-one-dimensional FS sheets with a certain
degree of nesting would explain the development of AF
correlations and would be compatible with the two-fold
azimuthal AMRO. Notice that according to Ref. [25] the
rotation of the RuO$_6$ octahedra is expected to seriously
reduce the occupation of the $\gamma$ band. In any case, this un-
usual polar AMRO implies that high levels of Ca doping modifies the original FS of Sr$_2$RuO$_4$ at the point that it
no longer reveals a clear 2D character, in sharp contrast
with the ARPES measurements [12].

In order to understand the evolution of the FS as a
function of Ca doping, LDA calculations were done using
the LAPW method and the neutron crystal structures
[18] of $x = 0$ at 180 K (S0 short octahedra, Mott insula-
tor), of $x = 0$ at 400 K (L0, long octahedra, metal) and
$x = 0.5$ at 10 K (L5). For the S0 an antiferromagnetic
state, $m \sim 2\mu_B$ is predicted; the electronic structure has
very narrow bands at $E_F$, favorable for the observed Mott
insulating ground state. The L0 structure is an itinerant ferromagnet, $m \sim 1\mu_B$ in the LDA. Electric field gradi-
ents (EFG) are sensitive probes of orbital occupation.
A large change is found between the L0 and S0 structures:
the average Ru EFG’s are $-4.9 \times 10^{-21}$ V/m$^2$ and $+4.3 \times 10^{-21}$
V/m$^2$, for paramagnetic L0 and antiferromagnetic S0,
respectively. The L5 structure is weakly ferromagnetic,
preumably due to neglect of quantum critical fluctua-
tions in the LDA. $x = 0.2$ is on the borderline between
these two states, i.e. it is in a long octahedra structure
intermediate between L0 and L5, is on the verge of the
long to short crossover. The L0 FS is complex due to zone
folding and lowered symmetry, but, it has two contribu-
tions, heavy bands (H), that do not contribute to trans-
port and an itinerant component. The H-FS is strongly
affected by magnetic ordering, seen in a reduction by a
factor of more than 2 in the EFG (to $-2.3 \times 10^{-21}$ V/m$^2$)
when ferromagnetic, showing a change in orbital popula-
tion. This is accompanied by a large change in the den-
sity of states: $N(E_F) \sim 2.5$ eV$^{-1}$ per Ru per spin (para-
magnetic) $1.3$ eV$^{-1}$ (majority) and $2.9$ eV$^{-1}$ (minority),
even though the in-plane transport function $N_x^2$, which
reflects the itinerant sheets, is the same to better than
10% for the paramagnetic, ferromagnetic majority and
ferromagnetic minority FS’s. If the situation is the same
at $x = 0.2$ as expected, the implication is that at the meta-
magnetic transition the heavy part of the FS is removed
for majority carriers, consistent with the experimental
results.

In summary, the Fermi surface of the Ca$_{2-x}$Sr$_x$RuO$_4$
system is strongly dependent on $x$. The anomalous pol-
ar AMRO and the severe field-induced Fermi surface
reconstruction observed at the metamagnetic transition of
$x = 0.2$, could be evidence for localized d-electronic
states within the metallic phase seen for $0.2 \leq x \leq 0.5$.
This possibility is supported by our LDA calculations and
is consistent with the predictions of the orbital-selective
Mott-transition scenario.
